ABSTRACT

Patients with Autoimmune Polyendocrinopathy Candidiasis Ectodermal Dystrophy (APECED) are prone to chronic mucocutaneous candidiasis, which is often treated with azoles. The purpose of this study was to characterize the oral *Candida* populations from 16 Irish APECED patients, approximately half the total number identified in Ireland, and to examine the effect of intermittent antifungal therapy on the azole susceptibility patterns of *Candida* isolates. Patients attended between one and four clinical evaluations over a five-year period, providing oral rinses and/or oral swab samples each time. *Candida* was recovered from 14/16 patients and *Candida albicans* was the only *Candida* species identified. Interestingly, clinical diagnosis of candidiasis did not correlate with microbiological evidence of *Candida* infection at 7/22 (32%) clinical assessments. Multilocus sequence typing (MLST) analysis of *C. albicans* isolates recovered from the same patients on separate occasions identified the same sequence type each time. Fluconazole resistance was detected in isolates from one patient, and isolates exhibiting a progressive reduction in itraconazole and/or fluconazole susceptibility were identified in a further 3/16 patients, in each case correlating with upregulation of *CDR*- and *MDR*-encoded efflux pumps. Mutations were also identified in the *ERG11* and the *TAC1* genes of isolates from these four patients, some of which have previously been associated with azole resistance. The study suggests that alternative *Candida* treatment options, other than azoles such as chlorhexidine, should be considered in APECED patients and that clinical diagnosis of oral candidiasis should be confirmed by culture prior to the commencement of anti-*Candida* therapy.

INTRODUCTION

Autoimmune Polyendocrinopathy Candidiasis Ectodermal Dystrophy (APECED) is a monogenic autosomal recessive genetic disease caused by mutations in the *AIRE* (AutoImmune REgulator) gene that plays a role in induction of T cell tolerance in the thymus, and is located on human chromosome 21q22.3 (21, 63). To date, more than 60 different mutations have been reported worldwide in this gene, particularly in Finnish, Sardinian and Iranian Jewish populations (7).

The disease is characterized by autoimmunity to endocrine organs, ectodermal disorders such as hypoplasia of dental enamel, pitted nail dystrophy and alopecia, and chronic mucocutaneous candidiasis (CMC). The latter of these features is one of the three major clinical signs that define the syndrome, along with hypoparathyroidism and Addison's disease. Typically, CMC is the first manifestation and most common feature of APECED often occurring before the age of five, and may affect nails, mucous membranes and skin. Mucocutaneous candidiasis can present clinically as pseudomembranous candidiasis, erythematous candidiasis, or chronic hyperplastic candidiasis. These presentations may be accompanied by angular cheilitis, which may also present on its own. Several cases of oral carcinoma have been associated with CMC of the oral cavity and esophagus in these patients (4, 24, 45, 47). To date, a comprehensive analysis of the prevalence of oral *Candida* species in patients with APECED is lacking, however, a study of Finnish APECED patients by Rautemaa *et al.* (46) recovered oral *Candida* from 42/56 (75%) of the patients investigated. *Candida albicans*, the most commonly identified *Candida* species in humans, was identified in 35/56 (63%) of the APECED patients. Non-*C. albicans Candida* species were recovered from 7/56 (13%) APECED patients examined (46).

Because of the high prevalence of CMC in APECED patients, lifelong management of candidiasis is frequently required, typically by intermittent treatment with prophylactic topical and/or systemic azole antifungal drugs (46). The application of a similar candidiasis prophylaxis management strategy in human immunodeficiency virus (HIV)-infected or acquired immunodeficiency syndrome (AIDS) patients during the 1990s frequently resulted in the development of resistance to the triazole

antifungal fluconazole as well as cross-resistance to other azoles. Such cases are well documented in both *C. albicans* and other *Candida* species (11, 32, 61). The extensive use of prophylactic azole therapy in HIV-infected patients and other patient cohorts also resulted in the selection of *Candida* species with inherent reduced susceptibility to azoles such as *C. glabrata* and *C. krusei* (3, 22, 36). Since many APECED patients are routinely treated with antifungal agents, it is not surprising that azole resistance has also been reported in isolates recovered from them. Rautemaa *et al.* identified *C. albicans* isolates with decreased fluconazole susceptibility (fluconazole MIC 4–32 μg/ml) in 11/56 (20%) Finnish APECED patients. The same study also reported reduced fluconazole susceptibility in non-*C. albicans* isolates recovered from two APECED patients (46).

Due to their predominantly clonal mode of reproduction, the population structure of pathogenic *Candida* species can provide useful epidemiological information regarding the provenance of isolates exhibiting antifungal drug resistance, as well as predicting common molecular mechanisms by which antifungal drug resistance is mediated. For example, multilocus sequence typing (MLST) has identified the presence of 17 main clades in the population structure of *C. albicans*, of which clade 1 has been associated with flucytosine resistance due to a common mutation in the *FUR1* gene encoding uracil phosphoribosyltransferase that has spread throughout this clade (16, 35, 43). In *Candida dubliniensis* a MLST clade C3-specific mutation in the *FCY1* gene encoding cytosine deaminase has also been shown to confer high-level flucytosine resistance (29, 30). The population structure of *C. albicans* is now well established according to the consensus MLST scheme, identifying diploid sequence types (DSTs) based on the nucleotide sequences of the *AAT1, ACC1, ADP1, PMIb* (formerly *MPIb*), *ALA1* (formerly *SYA1*), *VPS13* and *ZWF1* genes (6, 35). The online database currently contains allelic and epidemiological information on more than 1700 DSTs (http://calbicans.mlst.net/).

The molecular mechanisms of azole resistance in *Candida* species are well documented and are typically mediated by failure to accumulate intracellular concentrations of the drug due to upregulation of the *CDR*- or *MDR*- encoded efflux pumps, or by upregulation or conformational alteration of the

lanosterol demethylase azole target encoded by the *ERG11* gene (22, 23, 26, 32, 36, 38, 51). The most common mechanism of fluconazole resistance in clinical isolates of *C. albicans* is *CaCDR1* upregulation, which also confers resistance to itraconazole and ketoconazole (12, 52-54). An association between the mating type of *C. albicans* isolates and azole resistance has previously been observed, due to the proximity of the *MAT* mating type gene to the *TAC1* gene on chromosome 5 (14, 50). Gain of function (GOF) mutations occurring in the transcriptional activator *TAC1* gene have been shown to be responsible for upregulation of *CDR*-encoded efflux pumps (15, 50, 56). Similarly, GOF mutations in the *MRR1* transcriptional regulator gene have been associated with upregulation of the Mdr1 efflux pump in *C. albicans* and *C. dubliniensis* (18, 50).

The purpose of the present study was to correlate clinical signs of oral candidiasis with *Candida* species and cell densities, and to investigate the long-term prevalence and persistence of *Candida* species in a well-characterized Irish cohort of 16 patients with APECED, representing the majority of such patients identified in Ireland. The oral health of this group of APECED patients has previously been reported (28). MLST was used to determine whether the same isolate persists or becomes replaced in APECED patients over prolonged periods of time, particularly following azole treatment, and to identify any co-colonization of patients with more than one type of strain. The effect of intermittent and repetitive antifungal therapy on the azole susceptibility patterns of these isolates was also investigated.

MATERIALS AND METHODS

Study group. The study group consisted of 16 patients with APECED in Ireland who have been described previously (28), and who each had a confirmed mutation in the *AIRE* gene. This represented approximately half of such patients identified in Ireland (17). These 16 patients had at least one oral examination at the Dublin Dental University Hospital between 2005-2010. Ethical approval was obtained from St. James's Hospital, and the Adelaide and Meath Hospital, incorporating the National Children's Hospital research ethics committee, and also from the research committee at Our Lady's Children's Hospital, Crumlin, Dublin. A calibrated pediatric dentist carried out the majority of clinical examinations in 2005, with a follow up examination by another calibrated dentist in 2010. Patients who attended more than one clinical assessment were examined at intervals that were at least one month apart, however, the majority were separated by three-month intervals (Table 1). At each clinical assessment, patients underwent a clinical examination seated in a dental chair with a conventional dental light for illumination. The dentist undertook a standardized visual examination of the oral mucosa, periodontal tissues and teeth. A comprehensive dental, medical and drug history was recorded for each patient (Table 1).

Assessment of oral candidiasis and identification of *Candida* isolates. Lesions clinically diagnosed by the dentist as oral candidiasis were recorded according to both a descriptive classification of lesions according to Sitheeque and Samaranayake (57) and lesion sites in the oral cavity. Oral candidiasis clinical presentations included, pseudomembranous candidiasis, erythematous candidiasis and hyperplastic candidiasis. An additional *Candida*-associated lesion, angular cheilitis, was also recorded if clinically present. During the initial clinical examinations in 2005, a quantitative determination of oral *Candida* cell density was made using oral rinse samples. Patients voluntarily performed a 30 second oral rinse with 10 ml sterile water, which was then returned into a sterile container. Neat oral rinse samples and ten-fold dilutions prepared in sterile water were plated on CHROMagar Candida™ medium (CHROMagar, Paris, France) and incubated at 37°C for 48 h.

Following incubation, plates were examined and the number of colonies present on each plate and their colors and relative abundances recorded. Nitrogen-gassed VI-PAK sterile swabs (Sarstedt, Wexford, Republic of Ireland) were also used to sample the oral mucosa and any lesions suggestive of oral candidiasis. These were inoculated onto CHROMagar Candida™ medium and incubated as for oral rinse samples. Only swab samples were taken from patients who attended a follow up visit in 2010. Single-colony isolates were presumptively identified on the basis of colony color and morphology on this medium (34). Definitive identification was undertaken by determining their substrate assimilation profiles using the API ID 32C yeast identification system (bioMérieux, Marcy l'Etoile, France) as described previously (41). For the purposes of the present study, oral rinse samples from individuals that yielded ≥ 500 *Candida* CFU/ml were considered as microbiological evidence of *Candida* infection. Similar cutoff thresholds for differentiating between oral *Candida* carriage and infection have been used in previous studies (19, 39). In the present study, the threshold was defined based on clinical and microbiological analysis of oral candidiasis in a minimum of 20,000 patients attending the Dublin Dental University Hospital (DDUH) over the past 25 years. Control data obtained from the DDUH Oral Biosciences Clinical database showed that 100% of 91 oral-rinse samples taken from HIV-infected patients who were not receiving antiretroviral therapy and displaying clinical signs of oral candidiasis yielded ≥ 500 CFU/ml. In 96% of these samples, *Candida* cell densities >1000 CFU/ml. In contrast, 100% of 85 oral rinses obtained from normal healthy university students who were not receiving any medication and had no clinical signs of oral candidiasis yielded ≤ 500 CFU/ml, with 97% of these samples yielded ≤ 50 CFU/ml.

Routine *Candida* culture. *Candida* isolates were routinely cultured on YPD [1% (w/v) yeast extract, 2% (w/v) Bacto™ neo- peptone (Sigma-Aldrich Ireland Ltd., Dublin, Republic of Ireland), 2% (w/v) glucose; pH 5.5] agar or in YPD broth at 37°C. Liquid cultures were grown overnight at 37°C in an orbital incubator (Gallenkamp, Leicester, United Kingdom) with shaking at 200 rpm. Following primary plating on CHROMagar Candida™ medium, swabs were incubated in YPD broth containing 20

µg/ml chloramphenicol (Sigma-Aldrich) and incubated overnight 37°C at 200 rpm to enrich for *Candida*. Following incubation, cultures were diluted 1 in 1000 in sterile water and plated out on CHROMagar Candida™ medium and incubated as described above.

Chemicals, enzymes and oligonucleotides. Analytical grade or molecular biology-grade chemicals were purchased from Sigma-Aldrich Ireland Ltd. or Fisher Scientific Ltd. (Loughborough, United Kingdom). Enzymes were purchased from the Promega Corporation (Madison, WI, USA), Applied Biosystems (Warrington, United Kingdom) or Invitrogen (Biosciences Ltd., Dublin, Republic of Ireland). Fluconazole powder was a gift from Pfizer Central Research (Sandwich, United Kingdom), and itraconazole was a gift from Janssen Pharmaceuticals (Cork, Republic of Ireland).

Nucleic acid isolation. In order to isolate DNA from *C. albicans* isolates, cells from 1.5 ml of YPD overnight culture were harvested by centrifugation at 14,000 × *g*. These cells were resuspended in 200 µl cell breaking buffer [2 % (v/v) Triton X-100, 1 mM EDTA, 1 % (w/v) SDS, 100 mM NaCl, 10 mM Tris, pH 8] and were then transferred to a 2 ml screw capped tube (Sarstedt Ltd., Wexford, Republic of Ireland) containing 0.3 g of acid-washed glass beads (Sigma-Aldrich). Following the addition of 200 µl of a mixture of 24:24:1 phenol:chloroform:isoamyl alcohol, cells were disrupted in a BIO101FastPrep instrument (Qbiogene, Cambridge, United Kingdom) for 20 sec at speed 4, followed by centrifugation at 14,000 × *g* for 10 min. The aqueous phase was removed and extracted twice with an equal volume of 24:1 chloroform:isolamyl alcohol. Finally, the nucleic acids were precipitated by addition of 400 µl of 70% ethanol at −20°C. Purified DNA was collected by centrifugation at 14,000 × *g* for 10 min and was resuspended in 50 µl of sterile water.

For quantitative gene expression analysis, RNA was extracted from isolates that were grown in YPD broth in the presence of a sub-inhibitory concentration of fluconazole (0.06 µg/ml). The RNAs were extracted using the Qiagen RNeasy mini kit (Qiagen Science, West Sussex, United Kingdom), and were treated with the Ambion TURBO DNA-*free*™ kit (Applied Biosystems) according to the

manufacturer's instructions. The RNA samples were then reverse transcribed to cDNA using the Superscript II reverse transcriptase kit (Invitrogen).

ABC genotyping. Selected *C. albicans* isolates from each patient were assigned to genotypes A, B or C based on the nucleotide sequence of the internal transcribed spacer region of the 25S rRNA gene as previously described (27).

Determination of mating types. The mating type of *C. albicans* isolates recovered from each patient during the course of this study was determined by multiplex PCR according to Rustad *et al.* (48).

Multilocus sequence typing (MLST). At least one *C. albicans* isolate recovered from each patient at each clinical assessment was subjected to MLST analysis as previously described (5, 6, 59). Briefly, the seven gene loci *AAT1a, ACC1, ADP1, PMIb, ALA1, VPS13* and *ZWF1b* were amplified by PCR for each isolate. These PCR products were purified using a QIAquick 96-well PCR purification kit (Qiagen Science, MD) and were sequenced using the same primers that were used for amplification. Sequencing reactions were performed commercially at Source BioScience LifeSciences (Dublin, Republic of Ireland) using an ABI 3730*xl* DNA analyzer. Sequence analysis was performed by examination of chromatogram files using the ABI prism Seqscape software, version 2.6 (Applied Biosystems, Foster City, CA). Identification of genotypes, allelic profiles and diploid sequence types (DSTs) was achieved using the consensus *C. albicans* MLST website (http://calbicans.mlst.net/).

Susceptibility testing. All isolates that were recovered and stored from each APECED patient were streaked out on separate CHROMagar Candida™ plates containing fluconazole at 8 µg/ml and 16 µg/ml, and containing itraconazole at 1 µg/ml and 0.125 µg/ml, in order to carry out large scale, rapid screening of isolates for reduced susceptibility or resistance to azole drugs. These plates were incubated at 37°C for 48 h and were then examined for the presence/absence of yeast colonies in comparison to drug-free control plates. Definitive azole minimum inhibitory concentration (MIC) determinations for *C. albicans* isolates were performed in duplicate using broth microdilution assays according to the method of the Clinical and Laboratory Standards Institute (CLSI; formerly the National Committee for Clinical

Laboratory Standards) document M27-A2 (9). Fluconazole was titrated from a concentration of 64 μg/ml to 0.125 μg/ml and itraconazole was titrated from a concentration of 16 μg/ml to 0.03 μg/ml in RPMI 1640 medium (Sigma-Aldrich). MICs were determined as the lowest concentrations of the drug that reduced turbidity by 50% relative to the growth of the drug-free controls. Isolates exhibiting fluconazole MICs of ≥ 64 μg/ml were classed as resistant, between 16 and 32 μg/ml as dose-dependent susceptible, and of ≤ 8 μg/ml were classed as susceptible. Isolates exhibiting itraconazole MICs of ≥ 1 μg/ml were classed as resistant, between 0.25 and 0.5 μg/ml as dose-dependent susceptible, and of ≤ 0.125 μg/ml were classed as susceptible.

Gene expression analysis. Quantitative real-time PCR (qRT-PCR) was carried out according to standard protocols in order to monitor the relative gene expression of the *ERG11* gene and the *CDR1-, CDR2-* and *MDR1*-encoded efflux pumps in *C. albicans* isolates exhibiting reduced azole susceptibilities (Table 2), specifically isolates recovered from patients 1, 11, 12 and 16. This was undertaken in order to determine whether significant upregulation of these genes was associated with reduced azole susceptibility. These data were compared with those of the two fluconazole-susceptible control isolates (fluconazole MIC = 0.125 μg/ml), one of which was recovered during the second clinical assessment of patient 4 (P4V2), and the *C. albicans* reference strain, SC5314 (8). The comparative amplification efficiencies of primer pairs were compared to the amplification efficiency of the *ACT1* internal control primer pair (Table 2) prior to qRT-PCR using primer amplification efficiency plot analysis as previously described (40). RNAs were extracted from isolates that were grown in either the presence or absence of a sub-inhibitory concentration of fluconazole (0.06 μg/ml) in order to identify if any gene upregulation was constitutive or facultative. Quantitative real-time PCRs were carried out using 0.3 μM of each primer (Table 2), and FAST SYBR® Green Master Mix in an ABI 7500 Real-Time PCR System (Applied Biosystems) according to the manufacturers recommended protocols. Data analysis was carried out as described by Livak and Schmittgen (25), calculating $2^{(-\Delta CT)}$ values from the average C_T values

acquired from three replicates for both the test and *ACT1* genes. Each qRT-PCR analysis was carried out in duplicate on two separate occasions.

The expression data for each gene was normalized to the expression of the *ACT1* gene for each isolate, which functioned as an internal control. The average $2^{(-\Delta CT)}$ values were obtained for isolates recovered from each patient in both the presence and absence of fluconazole, and were compared to the average $2^{(-\Delta CT)}$ value obtained from the fluconazole-susceptible control isolates, P4V2 and SC5314, also in both the presence and absence of fluconazole. Two tailed Student's *t* tests were carried out in order to assess the significance of the data.

Sequence Analysis of the *ERG11* and *TAC1* genes. The complete open reading frames (ORFs) of the *CaERG11* and *CaTAC1* genes (Genbank Accession numbers DQ903898.1 and DQ837377, respectively) were amplified using the pairs of oligonucleotides primers (Sigma Genosys Biotechnologies Europe Ltd., Cambridgeshire, United Kingdom) listed in Table 2. These genes were amplified from the DNA of one isolate recovered from both the first and last clinical assessment of patients 1, 11, 12 and 16. Sequence data was compared between each of two isolates recovered per patient in order to correlate any mutations with increased expression of *CDR*- encoded efflux pumps between clinical assessments. The nucleotide sequence of the *ERG11* gene was examined in order to identify any polymorphisms that could be associated with azole resistance. All sequence data was also compared with those of the fluconazole-susceptible isolate (fluconazole MIC = 0.125 μg/ml) recovered during the second clinical assessment of APECED patient 4 (P4V2). Amplification reaction mixtures consisted of 0.2 μM concentrations of each deoxynucleotide triphosphate (Promega), 0.2μM of each primer, 1 U of Phusion® HotStart High-Fidelity DNA Polymerase (New England Biolabs Ltd., Hertfordshire, United Kingdom), 1X Phusion® HF Buffer (New England Biolabs Ltd.) and 100 ng of template DNA. These reaction mixtures underwent an initial denaturation step of 98°C for 1 min, followed by 35 cycles of 98°C for 30 s, 61°C for 30 s, 72°C for 3 min 30s, followed by a final elongation step of 72°C for 10 min. For amplification of the *CaERG11* gene, the repeated elongation

step was performed at 72°C for 2 min 30s instead of 3 min 30s. The *CaERG11* and *CaTAC1* amplification products were 2.5 kb and 3.7 kb in size, respectively. These products were purified using the Sigma GenElute™ PCR clean up kit (Sigma-Aldrich) and were sequenced commercially by Source Bioscience Lifesciences (Dublin, Republic of Ireland) using the sequencing primers (Table 2) and a 3730*xl* DNA analyzer. Nucleotide and amino acid sequence alignments were carried out using the CLUSTAL W2 sequence alignment computer program (60) available at the EMBL-EBI website (http://www.ebi.ac.uk/Tools/msa/clustalw2/).

RESULTS

Clinical assessment of oral candidiasis. Patients were clinically assessed at the Dublin Dental University Hospital on at least one occasion, during which a full medical history was taken and a complete clinical assessment of the oral cavity was carried out. Several patients had multiple clinical presentations of candidiasis at separate clinical assessments. At the initial assessment in 2005, 7/16 (44%), 11/16 (69%) and 7/16 (44%) patients displayed clinical signs suggestive of pseudomembranous candidiasis (PC), erythematous candidiasis (EC) and angular cheilitis (AC), respectively (Table 3). In total, 11/16 (69%) patients showed clinical signs of oral *Candida* infection, and oral *Candida* isolates were recovered from 12/16 (75%) patients (Table 3). At the second assessment, 4/11 (36%), 4/11 (36%) and 2/11 (18%) patients displayed clinical signs suggestive of PC, EC and AC, respectively (Table 3). In total, 5/11 (45%) showed clinical signs of oral *Candida* infection, and oral *Candida* isolates were recovered from 8/11 (73%) patients (Table 3). At the third assessment, 4/11 (36%), 4/11 (36%) and 4/11 (36%) patients displayed clinical signs indicative of PC, EC and AC, respectively (Table 3). In total, 6/11 (54%) showed clinical signs of oral *Candida* infection, and oral *Candida* isolates were recovered from 7/11 (64%) patients (Table 3). Individuals from whom ≥ 500 *Candida* CFU/ml of oral rinse were recovered were considered as having microbiological evidence of *Candida* infection. Clinical signs suggestive of candidiasis did not always correlate with microbiological evidence of infection. Throughout the three assessments, clinical signs suggestive of candidiasis were noted at 22 individual assessments of the 16 patients studied and oral *Candida* cell densities indicative of *Candida* infection (range 500 - >10,000 CFU/ml in oral rinse samples) were recovered from patients on 15/22 (68%) of these occasions (Table 3). A provisional clinical diagnosis of candidiasis was not supported by microbiological analysis of oral samples in the remaining 7/22 patient evaluations (32%), as *Candida* cell densities of between 0 and 380 CFU/ml were observed in oral rinse samples (Table 3). For example, at the first clinical assessment, patients 3, 6, 9 and 13 exhibited clinical signs suggestive of either pseudomembranous candidiasis, erythematous candidiasis, angular cheilitis, or a combination of more

than one of these conditions, despite the recovery of only 80, 70, 380, and 80 CFU/ml from these patients at this assessment, respectively (Table 3). At the second clinical assessment, 0 CFU/ml were recovered from patient 13 who exhibited clinical signs suggestive of erythematous candidiasis (Table 3). In contrast, at the third clinical assessment, patient 10 did not exhibit any clinical signs suggestive of candidiasis, yet oral rinse samples yielded a *Candida* density of 500 CFU/ml (Table 3). Data recovered from direct swab sampling of lesions suggestive of oral candidiasis in several individual APECED patients reflected the findings of oral rinse sampling but the yield of *Candida* recovered was on average five-times lower. It should be noted that swab samples of the oral cavity yield significantly lower densities of *Candida* CFU than oral rinse samples (10). Swabs used to directly sample oral lesions suggestive of erythematous candidiasis in patients 5, 6 and 10 during clinical assessments in 2010 all yielded less than 30 *C. albicans* CFU. For example, patient 5 exhibited clinical signs of erythematous candidiasis at the left buccal mucosa and palate, these were not supported by microbiological analysis of swab samples taken from these sites which yielded 5 and 14 cfu/swab, respectively (Fig. 1). In contrast, a swab used to directly sample a lesion of the right buccal mucosa suggestive of erythematous candidiasis in patient 15 in 2010 yielded 200 CFU.

Candida albicans was the only *Candida* species recovered from the APECED patients during the course of the study. Swabs used to sample the oral cavities of patients 5, 6, 10 and 15 during a follow up assessment in 2010 from which only *C. albicans* was recovered on CHROMagar Candida™ medium underwent overnight broth enrichment in order to recover any other *Candida* species that may be present at lower densities. This was unsuccessful for all four patients, and *C. albicans* remained the only *Candida* species to be identified.

Analysis of *C. albicans* population in patients with APECED. Isolates were recovered sequentially from 14/16 APECED patients during between one and three clinical assessments in 2005. A further follow up assessment was carried out on 11 of these patients in 2010 and further isolates were recovered from the oral mucosa or from lesions suggestive of oral candidiasis during these assessments.

A total of 54 of these *C. albicans* isolates recovered sequentially from 14/16 APECED patients underwent MLST analysis and ABC genotyping, in order to determine if isolates persisted or were replaced in patients with APECED throughout the course of the study.

A total of 18 different DSTs were identified by MLST from the 14 patients from whom *C. albicans* isolates were recovered (Fig. 2, supplemental material). Eight of these DSTs were previously identified and the remaining ten newly identified DSTs were added to the *C. albicans* MLST database. Isolates recovered at sequential clinical assessments were available for nine of the 14 *C. albicans*-positive patients, and MLST analysis yielded identical DSTs at each evaluation (Table 4), indicating long-term maintenance of the same DST over the five-year study period in these APECED patients. The remaining three patients yielded isolates of more than one DST. Eight isolates identified as DST 1778 were recovered from patient 1 on the first three clinical assessment visits (03/05, 06/05, 09/05), and two isolates identified as DST 1780 and DST 1224 were recovered from this patient at a follow up assessment (02/10) (Table 4). Two isolates identified as DST 1784 were recovered from patient 11 on the first two assessment visits (03/05, 09/05), and two isolates identified as DST 1785 were recovered from this patient on a follow up assessment in 2010 (Table 4). Isolates were recovered from patient 13 only on the first of three clinical assessments, however, isolates recovered from the first visit were identified as DSTs 1786 and 1787. In relation to patients who yielded *C. albicans* isolates with different DSTs, the differences between DSTs occurred at only one or two loci and in all cases, resulted from loss of heterozygosity at between two and nine nucleotides, indicative of microvariation or genotypic shuffling. A UPGMA dendrogram was constructed comparing the allelic profiles and DST data of the *C. albicans* isolates recovered during the course of this study with those previously reported by Odds *et al.,* (35). This was used to identify the MLST clade to which *C. albicans* isolates recovered from patients with APECED belonged. Isolates recovered from 5/14 patients belonged to MLST clade 1 (Table 4), the most predominant MLST clade in the population structure of *C. albicans*. The second most predominant clade in the present study was clade 4, to which isolates recovered from 3/14 patients belonged (Table

4). Isolates recovered from two patients belonged to clade 15, and the isolates recovered from the remaining patients belonged to clades 2 and 8. Isolates recovered from patients 13 and 15 were identified as singletons (Table 4).

Analysis of ABC genotypes of recovered isolates. The most predominant ABC type identified in isolates recovered from the 14 *C. albicans*-positive patients was genotype A, which was identified in isolates recovered from nine patients. Isolates recovered from one patient were identified as ABC genotype B, and isolates from the remaining four patients were identified as ABC genotype C (Table 4).

Azole susceptibility of isolates. The fluconazole and itraconazole susceptibilities of 62 and 59 *C. albicans* isolates recovered sequentially from 14 patients were also determined, respectively, according to the CLSI protocol M27-A2. Fluconazole resistance was exhibited by eight isolates (fluconazole MIC = 64 μg/ml), recovered sequentially from patient 12 during three separate clinical assessments (03/05, 09/05 and 10/05). Seven of these isolates also exhibited dose-dependent-susceptibility to itraconazole (itraconazole MIC = 0.5 μg/ml). Seven of these eight isolates were analyzed by MLST and identified as DST 315. Dose-dependent susceptibility (itraconazole MIC = 0.25 μg/ml) was also exhibited by isolates recovered from patient 16, despite the susceptibility (itraconazole MIC = 0.06 μg/ml) of an isolate recovered during an earlier assessment (05/05) of this patient (Table 5). All isolates recovered from this patient were identified as DST 519 (Table 4). The remaining isolates were all susceptible to both fluconazole and itraconazole (fluconazole MIC 0.125 – 2 μg/ml and itraconazole MIC 0.03 – 0.125 μg/ml), however, a gradual stepwise reduction in azole susceptibility was noted in isolates recovered from patients 1, 11 and 16 at sequential clinical assessments (Table 5). MLST analysis showed that the same DSTs persisted in each of these patients throughout these sequential clinical assessments (Table 4) undergoing microvariation rather than strain replacement.

The mating types of all isolates subjected to MLST analysis were also determined. All isolates examined were a/α at the *MAT* locus with the exception of certain isolates recovered from patients 1, 11 and 16 (Table 4). One isolate recovered from patient 1 was identified as α /α at the *MAT* locus, despite

being identified as the same DST as all other isolates recovered sequentially from this patient. Isolates recovered during the latter clinical assessments of patients 11 and 16 were identified as a/a at the *MAT* locus, in contrast to isolates recovered at earlier assessments (Tables 4 and 5). All patients from whom isolates exhibiting azole resistance or a gradual reduction in azole susceptibility were recovered were being treated with differing combinations of fluconazole, itraconazole or miconazole (Tables 1 and 5).

***CDR1* gene expression analysis.** The average *CDR1* expression was significantly higher in isolates recovered from patient 1, (average 2.3 fold, $p < 0.0005$), patient 12 (average 3.8-fold, $p < 0.00005$), and patient 16 (average 4.5-fold, $p < 0.05$) in comparison to the fluconazole-susceptible control isolates (Table 5). A highly significant ($p < 0.005$) 7.9-fold increase in *CDR1*-expression was observed in an isolate recovered from the fourth clinical assessment of patient 11, in comparison to isolates recovered from the same patient on the first and second clinical assessments. This increase in *CDR1* expression was 5.6-fold in comparison to the control isolates (Table 5). Patient 11 had recently completed a course of fluconazole therapy prior to the fourth clinical assessment (Table 5). No significant differences in *CDR1* expression were observed in isolates upon supplementation of growth media with fluconazole (Table 5).

***CDR2* gene expression analysis.** The average expression of the *CDR2* gene was upregulated an average of 30-fold in isolates recovered from patient 12 in comparison to the fluconazole-susceptible control isolates ($p < 0.005$). Isolates recovered from patient 16 also exhibited an average 4.2-fold increase in *CDR2*-expression ($p < 0.05$) in comparison to the control isolates (Table 5). A highly significant ($p = 0.0001$) 35-fold increase in *CDR2*-expression was observed in an isolate recovered from the fourth clinical assessment of patient 11, in comparison to isolates recovered from the same patient on the first and second clinical assessments (Table 5). This increase in *CDR2* expression was 33.8-fold in comparison to the control isolates (Table 5). This isolate had also exhibited a 7.9-fold increase in *CDR1*-expression. No significant difference in *CDR2*-expression was observed in isolates recovered from patient 1 in comparison to the fluconazole-susceptible control isolates (Table 5). No significant

differences in *CDR2* expression were observed in isolates upon supplementation of growth media with fluconazole (Table 5).

***MDR1* gene expression analysis.** Isolates recovered from patient 1 exhibited an average 3-fold increase in *MDR1* expression in comparison to the fluconazole-susceptible control isolates ($p < 0.0005$). No other significant increases in *MDR1*-expression were observed in isolates recovered from patients 11, 12 or 16 in comparison to the fluconazole-susceptible control isolates (Table 5). Neither were significant differences in *MDR1* expression observed in isolates upon supplementation of growth media with fluconazole (Table 5).

***ERG11* gene expression analysis.** No significant differences in *ERG11*-expression were observed between isolates recovered from patients 1, 11, 12 or 16 in comparison to the fluconazole-susceptible control isolates. The presence of fluconazole reduced the expression (range average 1.7 – 2.1-fold) of *ERG11* in all isolates recovered from patients 11 and 12 significantly ($p < 0.01$). No other significant differences were observed in isolates recovered from other patients.

Sequence Analysis of the *ERG11* and *TAC1* genes. The nucleotide sequence of the *TAC1* gene of eight isolates exhibiting reduced azole susceptibility or azole resistance was analyzed and compared to that of the fluconazole-susceptible isolate recovered from patient 4, P4V2. These eight isolates consisted of the first and last isolate recovered from each of patients 1, 11 12 and 16. Previous studies have shown that mutations often accumulate over time in genes associated with reduced azole susceptibility such as *TAC1* and *ERG11* in *C. albicans* isolates recovered sequentially from individual patients receiving recurrent azole therapy (33, 50). Twelve amino acid substitutions were identified in the *TAC1* gene of these eight isolates that were not present in the nucleotide sequence of the fluconazole-susceptible P4V2 isolate (Table 5). One of these amino acid substitutions, A736V, has previously been identified as a GOF mutation in the *TAC1* gene of clinical *C. albicans* isolates, leading to upregulation of the *CDR*-encoded efflux pumps (15). This substitution occurred in the last isolate recovered from patient

11 during a follow up clinical assessment in 2010, and correlated with significant constitutive upregulation of the *CDR1* and *CDR2* genes (Table 5).

Isolates recovered from patient 12 exhibited fluconazole resistance and dose-dependent susceptibility to itraconazole (Table 5). Although eight amino acid substitutions were identified in the *TAC1* gene of these two isolates (Table 5), none of these have been definitively associated with *CDR*-upregulation. Three amino acid substitutions were identified in the *ERG11* gene of these two isolates also, one of which (S405F) has previously been associated with azole resistance (33).

Amino acid substitutions were also identified in the *ERG11* and *TAC1* genes of isolates recovered from patient 1, and in the *TAC1* gene of isolates recovered from patient 16 (Table 5), however, none of these mutations have been definitively associated with azole resistance.

In total, six amino acid substitutions were identified in the *ERG11* gene of the eight isolates examined that were not present in the fluconazole-susceptible isolate P4V2. All of these six substitutions had previously been reported (33), however only the S405F substitution (Table 5) which was observed in both isolates sequentially recovered from patient 12, has been directly associated with azole resistance (33).

DISCUSSION

Although oral candidiasis is well established as one of the primary features of APECED, complete and in-depth analyses of the *Candida* populations in these patients is mostly lacking. To date, a search of the literature revealed only two studies regarding the prevalence and population structures of *Candida* species recovered from patients with APECED. These two studies have both been published by the same group of researchers and are based on APECED patients in Finland (46, 56). The purpose of the present study was to carry out a thorough and in-depth analysis of the *Candida* species recovered from approximately half of the APECED patients definitively identified in Ireland (17). These patients were assessed at the Dublin Dental University Hospital over a period of five years, and the clinical signs of candidiasis as diagnosed by an experienced oral medicine physician were correlated with microbiological evidence of *Candida* infection. Two interesting findings resulted from this analysis; the first was that clinical signs suggestive of oral candidiasis were not supported by microbiological evidence of candidiasis on a total of 7/22 (32%) occasions in six individual patients. Similarly, direct sampling of lesions suggestive of erythematous candidiasis yielded very low *Candida* counts and did not support microbiological evidence of candidiasis in several patients during the follow up clinical assessment in 2010. This suggests that the cause of these clinical signs on these occasions was not due to *Candida* infection, but may have been due to infection with other microbial agents such as bacteria or viruses. Alternatively the clinical lesions suggestive of oral candidiasis may have been due to abnormal T cell proliferation in these patients, leading to an exaggerated immune response to environmental stimuli such as the presence of yeast pathogens at low levels, as previously observed in *AIRE*-deficient mice (44). Further histological, immunological and microbiological investigation of such non-*Candida* associated oral mucosal lesions is therefore warranted.

APECED patients are often prescribed systemic or topical antifungal therapy prophylactically to control oral candidiasis, often based on the provisional clinical diagnosis of candidiasis and without prior microbiological confirmation. This is probably an unwise practice in light of past experience with the

development of azole-resistance in *Candida* species in HIV-infected and AIDS patients receiving azoles prophylactically (1, 49, 62).

The second interesting feature observed during the course of the study was the monospecies colonization of the oral cavities of these APECED patients with *C. albicans*. *Candida albicans* is the most common cause of all types of candidiasis. However, during the 1990s other *Candida* species such as *C. glabrata, C. parapsilosis C. tropicalis, C. krusei* and *C. dubliniensis* were associated with superficial and systemic infection more frequently, particularly in HIV-infected and AIDS patients who were receiving azole treatment (11, 13, 42, 58). Antiretroviral treatment has reduced the rates of opportunistic fungal infections in HIV-infected patients, however, non-*C. albicans Candida* species are still frequently associated with candidiasis in immunocompromised patients (20, 37, 55, 64). In particular, *C. glabrata* and *C. krusei* are often selected for in patients receiving azole therapy due to intrinsic or acquired reduced azole susceptibility (3, 22, 31, 36, 64). It is therefore very surprising that only *C. albicans* was recovered from the APECED patients, despite the fact that they received frequent antifungal therapy, not only with azoles (11/16 (69%) of patients), but also with the polyene antifungal drug nystatin (Table 1). In the present study, broth enrichment of oral swab samples from four patients harboring *C. albicans* was undertaken in an attempt to recover non-*C. albicans* isolates potentially present at low abundance in the original samples. However, no non-*C. albicans* isolates were recovered. An analysis of the *Candida* population in a group of Finnish patients with APECED reported the recovery of non-*C. albicans Candida* species in 7/56 (12.5%) patients investigated (46), however, the identity of these species was not stated. Given the relatively low level of non-*C. albicans Candida* species in the Finnish study, the most likely reason for the *C. albicans* monospecies colonization observed in our study group may be a result of the small size of the patient population available for study, although approximately half of the Irish population with APECED was represented (17).

The susceptibility of sequentially recovered isolates to fluconazole and itraconazole was examined using agar containing azoles at breakpoint concentrations, as well as using broth microdilution

assays. In total, 11/16 (69%) of the APECED patients examined in the present study are currently known to be receiving treatment with fluconazole or itraconazole. Four of these 11 patients (36%) yielded isolates that exhibited either azole resistance or a gradual reduction in azole susceptibility. Broth microdilution assays identified the presence of isolates exhibiting fluconazole resistance and dose-dependent susceptibility to itraconazole in patient 12. This patient is currently 39 years old and has been treated with both topical and systemic azole therapy for many years. Two isolates recovered from this patient exhibited significant upregulation of the *CDR1* and *CDR2* genes. Eight amino acid substitutions were identified in the *TAC1* gene of these two isolates (Table 5), although none of these have been definitively identified as GOF mutations. Three amino acid substitutions were also identified in the *ERG11* gene of these two isolates also, one of which (S405F) has previously been associated with azole resistance (33). This suggests that the azole resistance exhibited by the isolates recovered from this patient is possibly mediated by multiple factors. Isolates recovered sequentially from patient 11 exhibited a gradual reduction in fluconazole susceptibility, and isolates recovered sequentially from both patients 1 and 16 exhibited a gradual reduction in susceptibility to both fluconazole and itraconazole (Table 5). These patients were also regularly treated with both topical and systemic azole drugs (Table 1). Although the MICs exhibited by these isolates were below the susceptible MIC breakpoints, gradual increases in *CDR1*, *CDR2*, and *MDR1* expression correlated with the gradual reduction in azole susceptibility. A GOF mutation (A736V) in the *TAC1* gene that has previously associated with *CDR*-upregulation was identified in an isolate recovered from patient 11 in 2010 (Table 5). This mutation was not present in an isolate recovered from this patient in 2005, and the acquisition of this mutation correlated with significant upregulation of the *CDR1* and *CDR2* genes. Amino acid substitutions were also identified in the *TAC1* and *ERG11* genes of isolates recovered from patient 1 and 16, although none of these have been definitively identified as GOF mutations. It is possible that similar GOF mutations in the *MRR1* gene are responsible for the *MDR1*-upregulation exhibited by isolates recovered from patient 1.

MLST analysis of isolates recovered sequentially from 9/16 of these patients showed that the same isolates persisted for prolonged periods of time, undergoing minor genetic variation rather than strain replacement, and azole susceptibility testing demonstrated that persistent isolates develop azole resistance gradually, rather that undergo replacement with resistant isolates. Similar findings were recently reported with *C. albicans* isolates from Finnish APECED patients (56).

The present study has demonstrated for the first time that clinical signs of candidiasis did not correlate with microbiological evidence of infection in 32% of clinical assessments carried out on Irish APECED patients. It should be noted that two calibrated dentists at the Dublin Dental University Hospital carried out these clinical assessments individually, and that in both cases reporting of clinical signs indicative of oral candidiasis did not always correlate with microbiological culture-based evidence of *Candida* infection. The present study highlights the necessity for microbiological as well as clinical diagnosis of candidiasis prior to the commencement of antifungal therapy in APECED patients. Many of these patients are prescribed azoles prophylactically, a clinical practice that is probably best avoided. The use of regular topical treatments with biocides such as chlorohexidine may provide a more beneficial long-term prophylactic measure for controlling oral *Candida* in this patient cohort, as has been previously reported for HIV-infected children (2). Patients should only be prescribed antifungal therapies with azoles following microbiological culture analysis and confirmation of candidiasis to prevent the development of azole resistance in isolates persisting in these patients. This can be easily accomplished as microbiological evidence of candidiasis can be observed on CHROMagar Candida™ medium following incubation at 37°C for as little as 24 h. Furthermore, this diagnostic process enables presumptive species identification, which should also be taken into account when prescribing antifungal agents due to the reduced susceptibility of some *Candida* species to azoles (3, 22, 36).

TABLE 1. Patients with APECED included in the study

Patient	Sex	Age[a]	Clinical Assessment dates (month/year)	Medical history[b] -Age at diagnosis	Drug therapies
1	M	7	03/05 06/05 09/05 02/10	AI-6, AH-7	Fludrocortisone, itraconazole, nystatin, miconazole
2	F	15	02/05	NAD	Nil
3	M	18	02/05 03/10	HPT-13, AI-16, AH-3	Hydrocortisone, fludrocortisones, nystatin
4	F	17	03/05 07/05 10/05 09/10	HPT-3.5, AI-8.5	Prednisolone, fludrocortisones, miconazole, fluconazole
5	M	14	04/05 05/05 07/05 05/10	HPT-7, AI-7, Di-4, GI	Hydrocortisone, fludrocortisone, miconazole, fluconazole
6	F	14	02/05 05/05 08/05 07/10	HPT-7, AI-11	Fludrocortisone, hydrocortisone, nystatin, beclomethasone
7	F	6	02/05 06/05 12/05 09/10	HPT-5, A, GI	Nystatin
8	M	2	02/05 06/05 12/05 09/10	HPT-2, AI-2, GI	Fludrocortisone, nystatin, fluconazole
9	M	11	02/05	HPT-5, AI-8, GI	Itraconazole, fluconazole, nystatin, miconazole
10	M	15	03/05 05/05 06/05 07/10	HPT-6, A	Nil
11	M	9	03/05 09/05 10/05 04/10	AI-6	Fludrocortisone, hydrocortisone, miconazole, fluconazole
12	F	39	03/05 09/05 10/05	HPT-2, Di-28, A	Insulin, miconazole, nystatin, fluconazole, itraconazole
13	F	13	03/05 05/05 09/05	HPT-8, AI-12, A, GI	Fludrocortisone, prednisilone, nystatin, itraconazole
14	F	7	08/05 05/10	HPT-3.5	Miconazole, fluconazole
15	F	21	04/05 09/10	HPT-2.5, AI-8	Fludrocortisone, hydrocortisone, prednisilone, miconazole, nystatin, fluconazole
16	F	15	05/05 11/05 12/05	HPT-8, AI-9, A	Fluconazole, nystatin, itraconazole, fludrocortisone, hydrocortisone

[a]Age of patient when study first commenced

[b]Abbreviations: AI, adrenal insufficiency; AH, autoimmune hepatitis; NAD, no appreciable disease; HPT, hypoparathyroidism; Di, diabetes; GI, gastrointestinal disturbance; A, alopecia.

TABLE 2. Primers used in the present study

Primer name	Co-ordinates	Sequence (5′ - 3′)
		qRT-PCR primers
RT ACT1F	+ 1429 → + 1452	AGCTCCAGAAGCTTTGTTCAGACC
RT ACT1R	+ 1579 → + 1602	CCCAGGTATTGCTGAACGTATGCA
RT CDR1F	+ 4204 → + 4225	TGTGCTGAACGTGAATATGTTT
RT CDR1R	+ 4329 → + 4349	CTGTCAAATGAGTTCCACCAA
RT CDR2F	+ 4197 → + 4218	TTGTGCACCTAGAGAATTGGTT
RT CDR2R	+ 4358 → + 4380	CCATCAATGCTTTGTTTAGTCAA
RT MDR1F	+ 683 → + 705	GTGGTGCTAGTGTTGCTGATGTG
RT MDR1R	+ 747 → + 767	TTTGGGTGCTGTTTGTGGTCC
RT ERG11F	+ 686 → + 716	CCCCTATTAATTTTGTTTTCCCTAATTTACC
RT ERG11R	+ 774 → + 803	GAAAGAAATTAAACTGAGAAGAGAACGTGG
		Amplification primers
ERG11F	- 527 → - 511	ATTGTACGTGGCGCGAGGTACTAGAAA
ERG11R	+ 1899 → + 1924	CATCTGCTAATATAGGACCAGGATTCGAC
TAC1F	- 558 → - 532	GAAATTGTTAATGACGGTTCTACCTTC
TAC1R	+ 3192 → + 3217	TATTCATATACCCAACCGGAAATTGG
		Sequencing primers
TAC1F2	+ 256 → + 274	AATAAATCAACCGCCAATA
TAC1F3	+ 1117 → + 1133	ATTACCACCCCTGCTTC
TAC1F4	+ 1821 → + 1842	TTCCATATCCAATACTTTAGAA
TAC1R2	+ 423 → + 442	TATGCATCATTCTCGACATT
ERG11F2	+ 254 → + 273	TTATGTTATTAGGGAAAATT
ERG11F3	+ 988 → + 1009	CAAGATGTTATTTATCAAGAAG
ERG11F4	+ 1783 → + 1802	GAGGCGGAATCGGTTGATGG

Primer co-ordinates are numbered based on the adenine residue of the ATG start codon at the 5′ end of the *C. albicans* gene being designated +1.

TABLE 3. Clinical signs and *Candida albicans* density in the oral cavities of patients with APECED

Patient	OC[a]	Other CMC[b]	2005 (rinse) [c]								
			Clinical Assessment 1			Clinical Assessment 2			Clinical Assessment 3

[a] Patient has a history of oral candidiasis (OC).

[b] Patient has a history of chronic mucocutaneous candidiasis (CMC) apart from OC.

[c] Patients provided an oral rinse sample on at a minimum of one clinical assessment in 2005.

[d] Clinical signs of OC at time of clinical assessment.

[e] *Candida* density recovered in CFU/ml from oral rinse samples.

[f] Number of isolates stored from each visit for further analysis.

Blank fields indicate clinical assessments that were not attended by patients.

Abbreviations: Y, Yes; N, None; PC, pseudomembraneous candidiasis; EC, erythematous candidiasis; AC, angular cheilitis.

TABLE 4. Population analysis of *C. albicans isolates* recovered from APECED patients

Isolates examined	Clinical Assessment (Month/Year)	DST	ABC type	eBURST CC	UPGMA clade	MAT type
P1 V1 (n=3)	03/05	1778	A	1	1	α / α (n=1) a / α (n=2)

		1787	A	37	S	
P14 V1 (n=2)	08/05	363	C	S	4	a / α (n=2)
P15 V2 (n=3)	09/10	1220	C	17	S	a / α (n=3)
P16 V1 (n=1)	05/05	519	A	1	1	a / α (n=1)
P16 V2 (n=1)	11/05	519	A	1	1	a / a (n=1)
P16 V3 (n=1)	12/05	519	A	1	1	a / a (n=1)

Sequentially recovered isolates are defined according to patient number (P; 1-16) and clinical assessment number (V; 1-4). The number of isolates analysed from each clinical assessment per patient are indicated in parentheses. Clonal clusters (CCs) were assigned to MLST identified DSTs by eBURST analysis, and UPGMA clades were identified according to Odds *et al.* (35).

TABLE 5. Fluconazole and itraconazole MICs exhibited by isolates recovered sequentially from patients 1, 11, 12 and 16.

Patient	Azole therapy	MAT type	Clinical Assessment (Month/Year)	Isolates examined	MIC FLU (μg/ml)	Isolates examined	MIC ITR (μg/ml)	Isolates examined	Genes Significantly Upregulated ($p \leq 0.005$)	*ERG11*	*TAC1*

16	FLC ITC	a/α	05/05	1	0.125	1	0.06	3	*CDR1* (2.9), *CDR2* (6.4)		N772K
		a/a	11/05	1	1	1	0.25		*CDR1* (6.3), *CDR2* (4.9)		D776D/N
		a/a	12/05	1	1	1	0.25				

Average fold increases in gene expression values were obtained by comparing the average $2^{(-\Delta CT)}$ values for isolates recovered from each patient in both the presence and absence of fluconazole, to the average $2^{(-\Delta CT)}$ values obtained from the fluconazole-susceptible control isolates, P4V2 and SC5314 also in both the presence and absence of fluconazole. Amino acid substitutions identified in the *ERG11* and *TAC1* genes of isolates exhibiting reduced azole susceptibility that were not present in P4V2 are indicated. Mutations in the *TAC1* and *ERG11* genes that have previously been definitely associated with azole resistance in *C. albicans* are highlighted in bold typeface.

Abbreviations: MIC, Minimum inhibitory concentration; ITC, itraconazole; FLC, fluconazole; MC, miconazole.

FIGURE LEGEND

FIG. 1. Appearance of oral lesions indicative of erythematous candidiasis in an APECED patient in the absence of microbiological culture evidence. View of left buccal mucosa (panel **(A))** and palate (panel **(B))** taken from patient No. 5 at a follow up clinical assessment in 2010. Swab samples from these two sites yielded five (buccal mucosa) and 14 (palate) *C. albicans* CFU, respectively.
